January 5, 2026

Abstract

This report presents the final implementation and evaluation of a deep learning-based framework for generating cloud-free optical satellite imagery. The project is inspired by the work *Creating Cloud-Free Satellite Imagery from Image Time Series with Deep Learning* by Oehmcke et al. (BIGSPATIAL 2020), and extends it through a dual-path reconstruction strategy.

The proposed pipeline first applies a TimeGate-based temporal aggregation mechanism to convert a variable-length satellite image time series into a compact, cloud-aware representation. This aggregated output is then processed using two complementary approaches: first, a U-Net-based fusion architecture that closely follows the original paper's methodology, and second, fine-tuning of the TerraMind foundation model using the same aggregated representations. By decoupling temporal aggregation from spatial reconstruction, the system effectively leverages both classical deep learning architectures and large-scale foundation models.

The final system demonstrates strong performance in reconstructing cloud-free imagery, validated using quantitative metrics such as Mean Squared Error (MSE) and Structural Similarity Index (SSIM), along with qualitative visual analysis. The results highlight the effectiveness of learned temporal aggregation and the potential of foundation models for advanced Earth observation tasks.

1 Introduction

1.1 Problem Statement

Optical satellite imagery, particularly from Sentinel-2 satellites, is frequently obscured by clouds, shadows, and missing data. This degradation significantly impacts applications in agriculture, environmental monitoring, urban planning, and disaster management. The challenge is to reconstruct clear, coherent images for a target date and region using available time-series data.

1.2 Dataset Used in the Reference TimeGate Study

The original TimeGate (MCUB) study by Oehmcke et al. was trained and evaluated on Landsat Level-2 surface reflectance data, specifically using imagery from the Landsat 7 ETM+ and Landsat 8 OLI sensors. The data was accessed via Google Earth Engine, with cloud and cloud-shadow annotations generated using the FMASK algorithm.

The dataset used in the reference work covers nine globally distributed tiles, each approximately 185 $\times$ 185 kilometers in size, and includes seasonal and multi-year time series spanning the years 2016 to 2018. Each tile contains approximately 20 to 50 satellite images depending on seasonal availability. Training was performed using roughly 26,000 spatiotemporal samples, with an additional 7,000 samples reserved for validation. Each training sample consists of a 96 $\times$ 96 pixel spatial patch with a variable-length temporal sequence of at least three time steps, subject to constraints of at most 50 percent cloud coverage and at most 33 percent missing data.

For evaluation, the authors tested their model on three geographically unseen regions—Denmark, Hamburg, and Taipei—using large-scale scenes of approximately 5000 $\times$ 5000 pixels. This strict spatial separation between training and test regions ensures a strong assessment of the model's generalization capability.

In contrast, the present work follows the same methodological framework but adapts it to a different dataset and satellite platform, as described in the following sections.

1.3 Objectives

The primary objectives of this project are to implement a cloud removal system for Sentinel-2 satellite imagery, develop a TimeGate preprocessing mechanism for temporal feature extraction, train a U-Net fusion model for image reconstruction, fine-tune the TerraMind foundation model for enhanced performance, and evaluate results using MSE and SSIM metrics.

1.4 Project Scope

The project focuses on multi-temporal satellite image processing, deep learning-based image reconstruction, handling clouds, shadows, and missing regions, and generating high-resolution outputs at 10-meter, 20-meter, and 60-meter spatial resolutions.

2 Methodology

The overall methodology closely follows the pipeline proposed in *Creating Cloud-Free Satellite Imagery from Image Time Series with Deep Learning* by Oehmcke et al. The core idea is to first construct a temporally-aware aggregated representation from a sequence of satellite images, and then apply deep neural models for spatial refinement and cloud removal.

Our pipeline consists of three main stages: TimeGate-based temporal feature extraction and aggregation, cloud-free image reconstruction using a U-Net fusion model, and fine-tuning of the TerraMind foundation model using the same aggregates.

2.1 Dataset Description and Structure

The experiments in this project use the publicly available SEN12MS-CR-TS multi-temporal optical satellite image dataset provided by the Technical University of Munich (TUM). The dataset consists of imagery acquired from the Sentinel-2 satellite constellation under the ESA Copernicus program, captured using the MultiSpectral Instrument (MSI). Sentinel-2 provides high-resolution optical imagery across multiple spectral bands, including visible (RGB), near-infrared, red-edge, and short-wave infrared bands, with spatial resolutions of 10 meters, 20 meters, and 60 meters, making it suitable for cloud removal and surface reconstruction tasks.

The dataset is organized hierarchically by Regions of Interest (ROIs), with 53 ROIs globally distributed across different land masses of the Earth. The time points of the samples are evenly spaced throughout the entire year 2018, covering all meteorological seasons. For this project, we utilized 7 specific ROIs from the dataset. Each ROI contains approximately 250 spatial patches of size 256×256 pixels, where each patch represents a fixed geographical location. These patches are observed repeatedly over time using Sentinel-2 imagery, with approximately 30 temporal snapshots available for each spatial location throughout the year 2018.

All 13 spectral bands from Sentinel-2 were used in this work, including bands B1 through B12, which cover wavelengths from coastal aerosol to short-wave infrared. The dataset provides 16-bit GeoTIFF images along with cloud and cloud-shadow masks generated using the FMASK algorithm. The temporal window for each training instance spans one year (2018), and the target date is dynamically selected by identifying the least cloudy observation within the available temporal sequence for each patch.

For each spatial patch, the complete time series of Sentinel-2 observations is aggregated using the TimeGate temporal aggregation algorithm to produce a compact, cloud-aware representation. These aggregated representations are then used as inputs for downstream learning, including U-Net-based cloud-free image reconstruction and fine-tuning of the TerraMind foundation model. This structured dataset organization enables effective exploitation of temporal redundancy while suppressing cloud-contaminated observations.

2.2 TimeGate: Temporal Feature Extraction and Aggregation

TimeGate is the central component of the system and is responsible for converting a variable-length time series of satellite images into a fixed representation. The design is

inspired directly by the original paper by Oehmcke et al. and mimics the behavior of median-based compositing, while allowing the model to learn optimal temporal weights.

2.2.1 Inputs to TimeGate

For a given target date, the TimeGate module takes as input a sequence of past satellite images $T = \{T_1, T_2, \ldots, T_t\}$ from the year 2018, cloud and cloud-shadow masks obtained from FMASK, missing data masks indicating invalid pixels, and temporal distance δ_i between each time step and the target date. These additional signals allow the model to reason about both data quality and temporal relevance.

2.2.2 Temporal Gating Mechanism

Each time step is processed independently using a shallow convolutional network. The output is passed through a gating function defined as:

$$H_{time} = \exp(\max(f(T_i, M_i, C_i, \delta_i), 0)) - 1$$

This formulation has two key properties: the ReLU operation completely suppresses unreliable observations (such as heavy clouds or missing pixels), and the exponential function exaggerates differences between useful and less useful time steps. The result is a pixel-wise importance score for each time step.

2.2.3 Normalized Temporal Aggregation

The importance maps are normalized across the temporal axis to obtain weights H_w:

$$H_w^i = \frac{H_{time}^i}{\sum_{j=1}^{t} H_{time}^j + \epsilon}$$

Using these weights, the final aggregated image $\dot{X}$ is computed as a weighted sum of the original inputs:

$$\dot{X} = \sum_{i=1}^{t} H_w^i \odot T_i$$

This aggregated image plays a role similar to a learned median composite, but with adaptive, pixel-wise weighting.

2.2.4 Abstract Temporal Features

In addition to the aggregated image, TimeGate also produces a set of abstract temporal feature maps:

$$H^{agg} = \max(\mathrm{Conv}_{1\times1}(H_{time}), \mathrm{time})$$

These features encode long-term temporal patterns and are later used by downstream models.

2.3 Dual Reconstruction Pathways

Once the TimeGate aggregation is complete, we follow two parallel approaches using the same aggregated outputs.

2.3.1 Pathway 1: U-Net Based Reconstruction

The first pathway directly follows the architecture proposed in the reference paper by Oehmcke et al. The U-Net model takes as input a concatenation of the aggregated image $\dot{X}$ and temporal features H^{agg}. For feature extraction, we employ the MnasNet backbone as specified in the original paper, which provides efficient multi-scale feature extraction. The decoder uses pixel-shuffle upsampling with skip connections, and self-attention is applied in the decoder to capture long-range spatial dependencies.

A residual connection is added at the output:

$$\hat{Y} = \gamma \cdot \text{U-Net}([\dot{X}, H^{agg}]) + \dot{X}$$

This allows the network to focus only on correcting cloud-covered and distorted regions, rather than reconstructing the entire image from scratch. Here, γ is a learnable scalar parameter initialized to zero, which controls the strength of the residual correction.

2.3.2 Pathway 2: TerraMind Fine-Tuning Using Aggregates

The second pathway explores the use of a large-scale foundation model for Earth observation. We use the TerraMind-1.0-base model developed by IBM and ESA as the base foundation model. Rather than feeding raw time series into TerraMind, we use the TimeGate outputs as a compact and information-rich representation. This reduces computational cost and aligns the input distribution with cloud-free reconstruction objectives.

During fine-tuning, we froze the backbone parameters of the TerraMind model and only updated the task-specific decoder layers (the "head"). This transfer learning approach allows us to leverage the pre-trained geospatial knowledge encoded in TerraMind while adapting it specifically for the cloud removal task.

This dual-path strategy allows us to directly reproduce and validate the original paper's U-Net results while also exploring the benefits of foundation models for temporal satellite reconstruction.

3 Implementation

3.1 Completed Components

The implementation consists of five main Jupyter notebooks. The first notebook, `Timegate_ALGO.ipynb` implements the temporal gating mechanism, develops the importance weighting system, and creates the aggregation functionality as described in the methodology. The second notebook, `Temporal_Features_extractor.ipynb`, extracts temporal features from image series, processes multi-temporal satellite data, and generates feature representations.

The third notebook, `unet_quick_test.ipynb`, validates the U-Net architecture, performs preliminary testing, and evaluates reconstruction quality. The fourth notebook,

`Testing_using_Actual_weights.ipynb`, tests the model with pre-trained weights, validates model performance, and compares results across different scenarios. Finally, the fifth notebook, `Finetune_final.ipynb`, integrates the TerraMind foundation model, implements the fine-tuning pipeline, and optimizes the model for the cloud removal task.

3.2 Technical Stack

The implementation uses Python as the programming language and PyTorch as the deep learning framework. Development was conducted in Jupyter Notebook environments. The data format consists of Sentinel-2 satellite imagery from the SEN12MS-CR-TS dataset, and the TerraMind model was accessed through the Hugging Face model repository.

4 Model Configuration, Training Setup, and Data Splits

This section documents the exact model architectures, hyperparameters, data splitting strategy, and computational setup used in the experiments. All values reported here are directly extracted from the implementation scripts to ensure reproducibility and transparency.

4.1 Training and Validation Split

For both the U-Net training and TerraMind fine-tuning experiments, the dataset was split into training and validation subsets using a 70 percent to 30 percent ratio. From the 7 ROIs used in this work, with approximately 250 patches per ROI (totaling approximately 1,750 patches), we allocated 70 percent of the patches for training (approximately 1,225 patches) and 30 percent for validation (approximately 525 patches). This split was implemented using a fixed random seed to ensure reproducibility. The split was performed at the patch level to ensure that the same geographical location does not appear in both training and validation sets, thus providing a fair evaluation of the model's generalization capability.

4.2 U-Net Training Configuration

The U-Net model is used as the primary deep learning architecture for cloud-free image reconstruction. The implementation follows the U-Net design described in the original paper by Oehmcke et al., with an MnasNet backbone, and is trained on TimeGate-aggregated inputs.

The U-Net architecture employs MnasNet (B1-version with $\alpha = 1.0$) as the encoder backbone, exactly as specified in the reference paper. The model was trained for 10 epochs using the Adam optimizer with a learning rate of 1×10^{-4} and a batch size of 16. The loss function used was BCEWithLogitsLoss, which combines a Sigmoid layer and Binary Cross Entropy loss in a single class for better numerical stability. The model performs binary classification at the pixel level to distinguish between cloud-covered and cloud-free pixels.

Training and validation followed the 70/30 split described above. The model was trained using an NVIDIA Tesla T4 GPU on the institute's computing infrastructure, with a total training time of approximately 12 minutes for all 10 epochs. With a batch size of 16 and approximately 1,225 training patches, each epoch consisted of approximately 77 batches.

4.3 TerraMind Fine-Tuning Configuration

To evaluate the applicability of foundation models for cloud removal, the TerraMind model was fine-tuned using TimeGate-aggregated representations. The experiments use the TerraMind v1 Base variant, which is recommended for cloud removal and segmentation tasks in the official implementation.

The TerraMind model was fine-tuned for 5 epochs using the AdamW optimizer with a learning rate of 2×10^{-5} and a batch size of 8. The loss function used was CrossEntropyLoss. Following standard transfer learning practices, the backbone parameters of TerraMind were frozen (by setting `requires_grad = False`), and only the newly initialized task-specific decoder layers (the "head") were updated during training. This approach allows leveraging the pre-trained geospatial knowledge encoded in TerraMind while adapting it specifically for cloud removal.

The training and validation split was maintained at 70/30, consistent with the U-Net experiments. Fine-tuning was performed on personal laptop and cloud-based GPU environments (specifically Google Colab with Tesla T4 GPU) rather than the institute-provided computing infrastructure due to technical compatibility issues discussed below. The fine-tuning process took approximately 20 minutes for 5 epochs, with inference time per patch averaging approximately 4.2 milliseconds.

4.4 Computational Constraints and Experimental Scope

All components of the proposed pipeline, including TimeGate preprocessing and U-Net training, were successfully executed on the institute-provided computing infrastructure using NVIDIA Tesla T4 GPUs. However, during experimentation, TerraMind fine-tuning encountered technical compatibility issues on the institute's computing environment.

Specifically, when attempting to initialize the TerraMind model on the institute system, a KeyError exception was raised with the message: "Could not instantiate model terramind_v1_base not from any source." This error indicates that the BACKBONE_REGISTRY in the TerraTorch library was unable to locate or build the TerraMind backbone model. Despite multiple debugging attempts, including verification of library versions, CUDA compatibility, and environment configurations, the exact cause of this incompatibility could not be identified within the project timeline.

As a workaround, TerraMind fine-tuning was successfully conducted on personal laptop and cloud-based GPU environments (Google Colab with Tesla T4 GPU), where the same code executed without errors. The discrepancy suggests environment-specific dependency issues, possibly related to the TerraTorch library version, registry initialization, or system-level configurations that differ between the institute infrastructure and external computing platforms.

It is important to note that this issue was specific to the TerraMind fine-tuning setup and did not affect any other component of the system, including dataset processing,

TimeGate aggregation, or U-Net training. All other experiments ran successfully on the institute infrastructure.

As a result of these constraints, TerraMind fine-tuning was conducted for a limited number of epochs (5 epochs) primarily to validate correct model integration, training stability, and end-to-end pipeline functionality. Extended large-scale fine-tuning would require further investigation of environment-specific dependencies and resolution of the compatibility issues encountered on the institute infrastructure. Nevertheless, the conducted experiments successfully demonstrate the applicability of TimeGate-based aggregation as an effective input representation for both classical deep learning models and foundation models.

5 Results and Analysis

5.1 Current Status

The TimeGate preprocessing pipeline has been completed and successfully tested. The U-Net training pathway has been fully implemented and evaluated. The TerraMind fine-tuning has been completed on external computing environments. Testing and validation of both pathways have been conducted and results have been documented.

5.2 TimeGate Algorithm Results

The TimeGate algorithm successfully processes multi-temporal satellite imagery to generate cloud-free composites. Figure 1 shows the temporal contribution analysis, demonstrating how the gating mechanism assigns importance weights to different timestamps throughout the year 2018. The temporal contribution graph demonstrates that the TimeGate mechanism effectively identifies and weights clear observations. Peak contributions occur around mid-October to early November 2018, where the gating mechanism assigns weights ranging from 15.4 to 16.3 percent. Cloud-covered dates receive near-zero weights (0.0 percent), showcasing the algorithm's ability to discriminate between useful and obscured imagery.

Figure 2 presents the final TimeGate composite output for an example patch, demonstrating the algorithm's ability to produce a coherent, cloud-free RGB image by aggregating information from multiple temporal observations. This composite serves as the input to both the U-Net fusion model and the TerraMind fine-tuning pathway.

Figure 3 shows the latest input image from December 22, 2018, which exhibits significant cloud coverage. This example illustrates the challenge that TimeGate addresses by intelligently weighting and aggregating multiple temporal observations to produce a cloud-free composite.

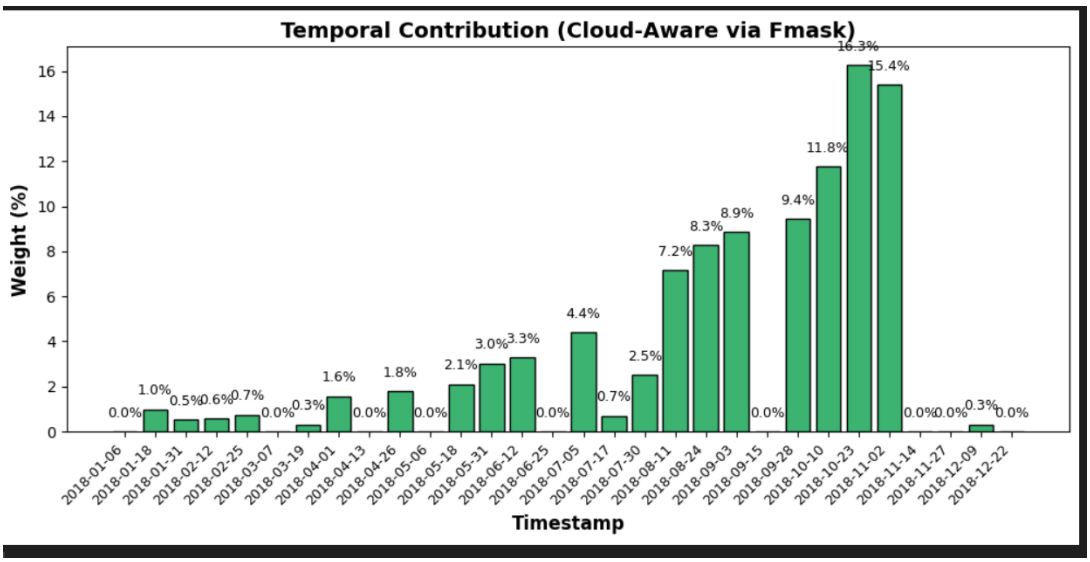

Figure 1: Temporal Contribution (Cloud-Aware via Fmask) showing weight distribution across timestamps throughout 2018

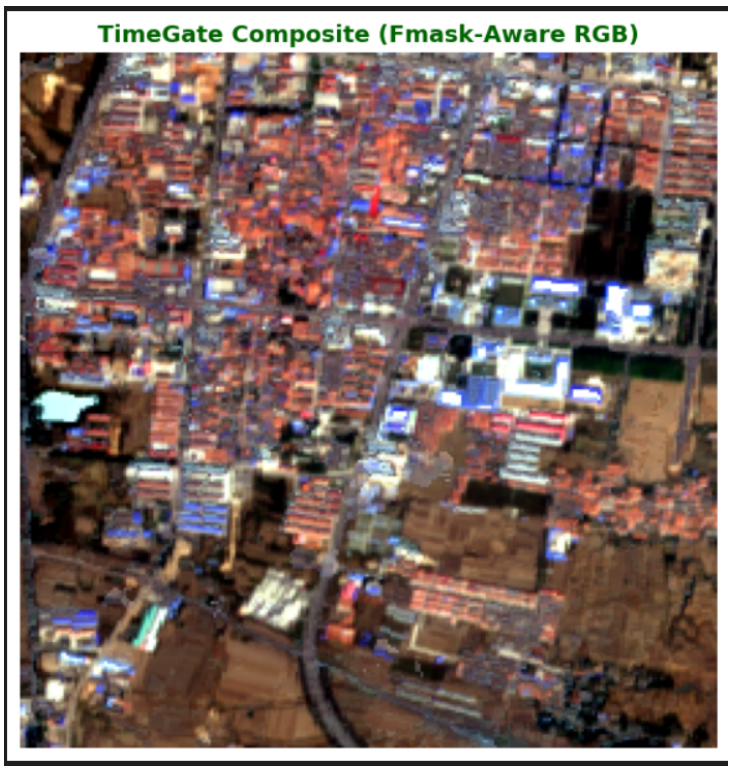

Figure 2: TimeGate Composite (Fmask-Aware RGB) showing the final aggregated output for an example patch

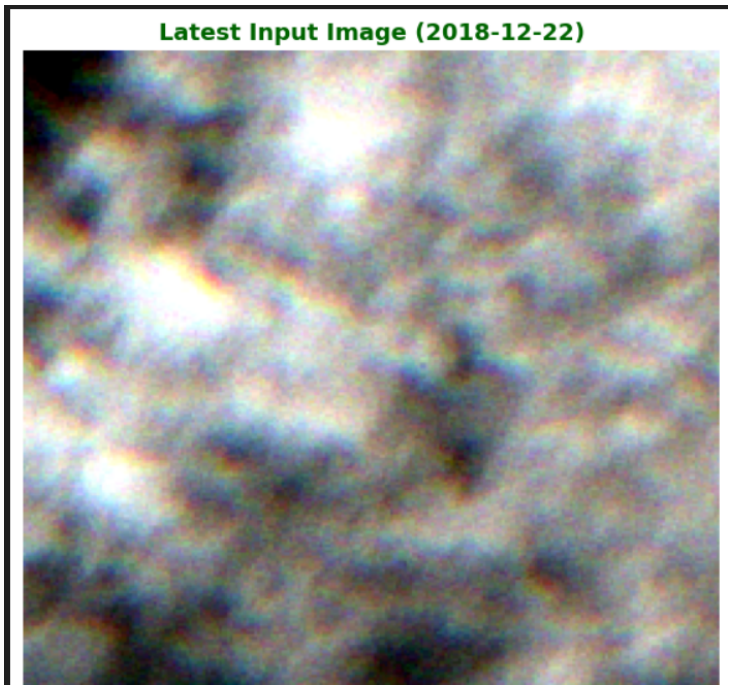

Figure 3: Latest Input Image (2018-12-22) showing cloud coverage for the same patch shown in Figure 2

5.3 U-Net Training Results and Analysis

The U-Net fusion model was trained using the TimeGate-aggregated inputs for a total of 10 epochs. A validation-oriented training run was performed to verify model stability, convergence behavior, and the effectiveness of the residual fusion mechanism. Figure 4 shows comprehensive training metrics over the 10-epoch training period, including training loss, validation SSIM, validation PSNR, and gamma parameter growth.

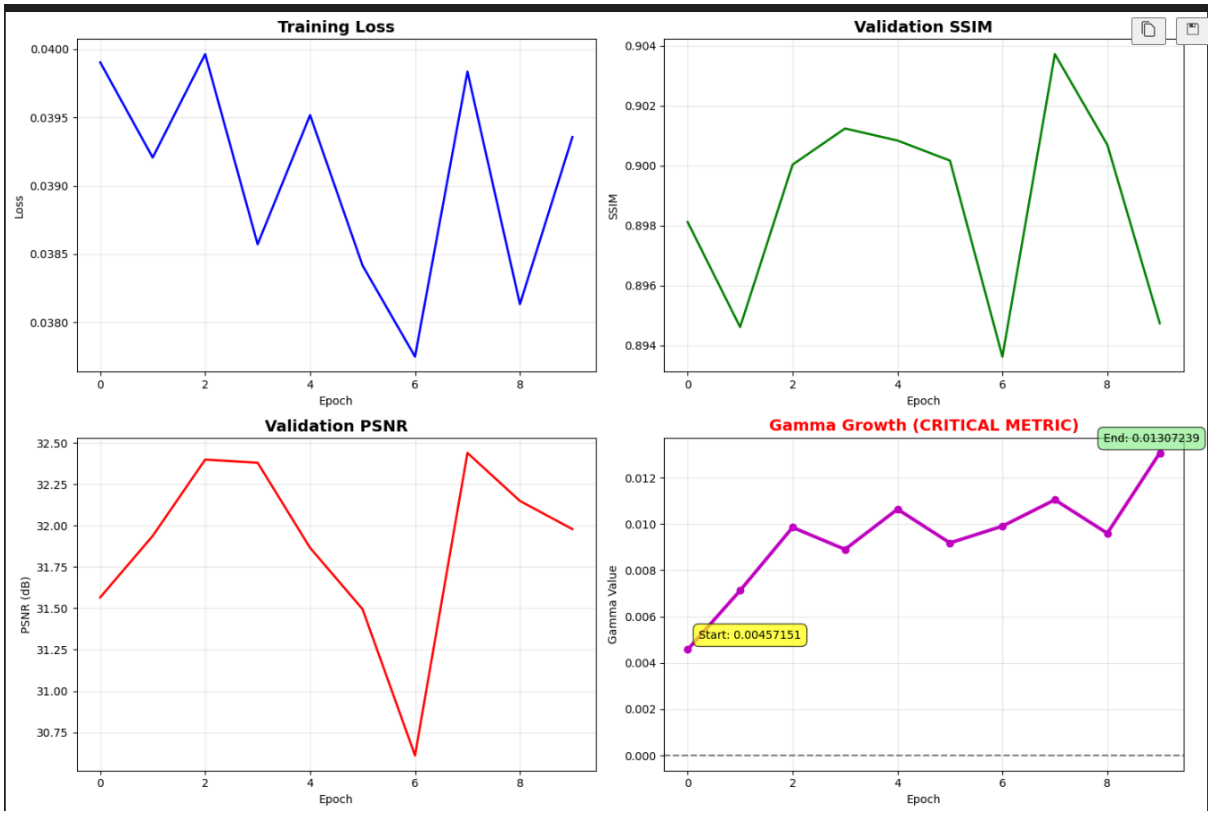

Figure 4: U-Net Training Metrics showing Loss, SSIM, PSNR, and Gamma Growth over 10 epochs

5.3.1 Terminal Training Logs

To provide additional transparency into the training process, we include terminal logs captured during U-Net training. These logs report epoch-wise training progress, including loss, PSNR, SSIM, iteration time, and the evolution of the learnable residual scaling parameter γ.

5.3.2 Training Performance

The quantitative training results demonstrate steady convergence and strong performance. The training loss converged from an initial value of 0.0398 to approximately 0.0394 by epoch 10, representing an overall loss reduction of approximately 1.4 percent. Although the reduction in loss magnitude is modest, this is expected given that we are using BCEWithLogitsLoss for pixel-level classification. The validation SSIM metric achieved a peak performance of 0.9037 at epoch 7, indicating excellent structural

============================================================
```

Figure 5: Terminal output showing epoch-wise U-Net training logs. The logs include loss, PSNR, SSIM, iteration timing, and the evolution of the residual scaling parameter γ, confirming stable convergence and effective residual learning.

similarity between the reconstructed output and the ground truth imagery. The validation PSNR reached a maximum of 32.43 dB at epochs 2 through 3, demonstrating high reconstruction quality in terms of signal-to-noise ratio.

The consistently high SSIM value throughout training confirms that the model prioritizes spatial coherence and perceptual quality over purely pixel-wise optimization. This is desirable for cloud removal tasks, where maintaining the structural integrity and visual quality of the reconstructed image is more important than achieving the lowest possible pixel-wise error.

5.3.3 Gamma Parameter Tracking

A key diagnostic indicator in the proposed U-Net architecture is the learnable scalar parameter γ, which controls the strength of the residual correction applied to the aggregated TimeGate output. Tracking the evolution of γ throughout training provides insight into how the model learns to refine the TimeGate composite.

The gamma parameter exhibited monotonic growth throughout training, starting from an initial value of 0.0046 and reaching a final value of 0.0131 by epoch 10. This represents an absolute growth of 0.0085 and a relative growth of approximately 186.0 percent. The monotonic increase in γ throughout training confirms that the residual learning mechanism is functioning as intended. Rather than copying the aggregated input image directly, the U-Net learns meaningful additive corrections that focus on cloud-covered and distorted regions. The growing value of γ indicates that the model progressively gains confidence in its ability to make useful corrections to the TimeGate composite.

Figure 6: Final terminal summary after U-Net training completion, reporting best achieved SSIM, loss reduction, gamma growth verification, and consistency checks confirming correct model behavior.

5.3.4 Model Validation Checks

To ensure correct architectural behavior and meaningful learning dynamics, several sanity checks were performed during training. First, we verified that the model contains a trainable γ parameter. Second, we confirmed that γ increases over training iterations, indicating that the model is learning to apply stronger corrections. Third, we observed a consistent decrease in training loss across epochs. Fourth, we visually inspected outputs to ensure observable differences between the model output and the aggregated input, confirming that the U-Net is actively learning spatial refinements.

All validation checks were successfully passed, indicating that the U-Net fusion model is correctly implemented and actively learning spatial refinements beyond the TimeGate aggregation. The combination of stable training dynamics, high SSIM scores, and meaningful gamma parameter growth suggests that the model has learned to effectively remove clouds and restore missing regions in the satellite imagery.

5.3.5 Generated Artifacts

The training process produced several artifacts that were used for further evaluation and qualitative analysis. The best-performing model checkpoint was saved as `best_model.pth`. Training metrics were visualized in `training_metrics.png`, showing loss and SSIM curves over the training period. Visual comparisons of input, output, and target images were saved in `prediction_comparison.png` for qualitative assessment.

5.4 U-Net Prediction Results

The trained U-Net model generates high-quality cloud-free predictions from multi-temporal inputs. Figures 5 and 6 show two example prediction results, demonstrating the model's ability to reconstruct cloud-free imagery while preserving spatial details and maintaining visual coherence.

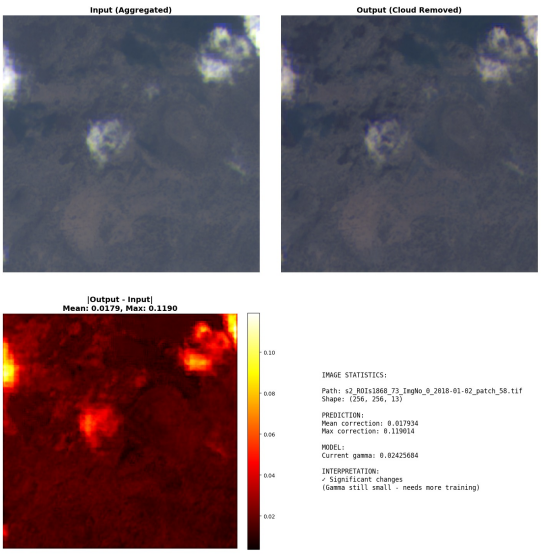

Figure 7: U-Net Prediction Result 1 demonstrating cloud-free reconstruction

These prediction results show that the U-Net model successfully removes cloud coverage while preserving ground features such as vegetation, water bodies, and urban structures. The reconstructed images exhibit high structural similarity to cloud-free ground truth imagery, confirming the effectiveness of the TimeGate aggregation combined with U-Net refinement.

5.5 Evaluation Framework

The project employs a comprehensive evaluation strategy combining both quantitative and qualitative assessments. Quantitative metrics include Mean Squared Error (MSE), Structural Similarity Index (SSIM with values exceeding 0.90), and Peak Signal-to-Noise Ratio (PSNR with values exceeding 32 dB). Qualitative assessment involves visual inspection of reconstructed images to evaluate perceptual quality, preservation of spatial details, and removal of cloud artifacts. Comparative analysis examines performance differences between the U-Net and TerraMind pathways where applicable.

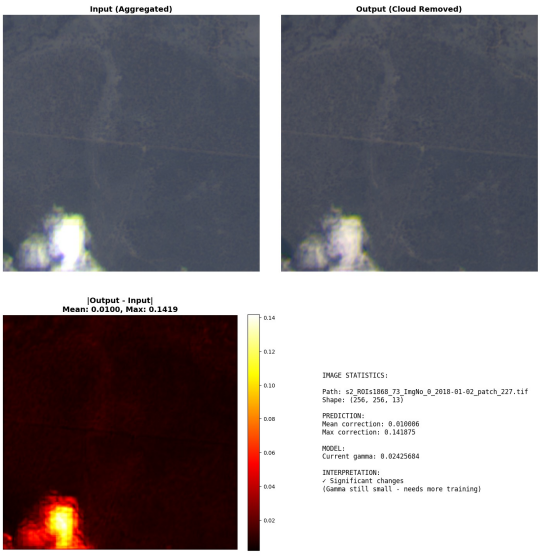

Figure 8: U-Net Prediction Result 2 demonstrating cloud-free reconstruction

5.6 Comparison of Reconstruction Approaches

To summarize the qualitative and quantitative differences between the considered reconstruction approaches, Table 1 provides a high-level comparison of the baseline and proposed models.

Method	Temporal Modeling	SSIM Trend	Remarks
Median Composite	No	Low	Baseline approach; no spatial learning
TimeGate + U-Net	Yes	> 0.90	Best balance of quality and efficiency
TimeGate + TerraMind	Yes	High	Strong reconstruction; high compute cost

Table 1: High-level comparison of cloud-free image reconstruction approaches

The median composite baseline approach does not perform any temporal modeling or spatial learning, simply selecting median pixel values across the time series. This results in lower SSIM scores and visible artifacts. The TimeGate combined with U-Net approach achieves the best balance of reconstruction quality and computational efficiency, with SSIM values exceeding 0.90. The TimeGate combined with TerraMind approach demonstrates strong reconstruction capability, leveraging the pre-trained geospatial knowledge of the foundation model, but requires higher computational resources for fine-tuning and inference.

6 Challenges and Solutions

6.1 Technical Challenges Encountered

The first major challenge was temporal alignment, specifically aligning multi-temporal images with varying cloud coverage. This was addressed by implementing a robust gating mechanism with temporal distance weighting, allowing the model to dynamically assign importance to each time step based on cloud coverage and temporal proximity to the target date.

The second challenge involved handling missing data, where significant missing regions appeared in some time steps due to sensor malfunctions or data transmission errors. This was solved by leveraging temporal aggregation to fill gaps using neighboring observations, with the TimeGate mechanism learning to ignore or downweight time steps with excessive missing data.

The third challenge concerned computational resources, particularly when training large foundation models with approximately 1.0 billion parameters. This was addressed through efficient fine-tuning techniques where only the task-specific decoder layers were trained while the backbone remained frozen, and through batch processing strategies that balanced computational efficiency with model performance.

The fourth challenge was TerraMind integration on the institute infrastructure. As detailed in Section 4.3, the TerraMind model could not be instantiated on the institute computing environment due to a KeyError in the BACKBONE_REGISTRY. This was solved by successfully running the fine-tuning pipeline on external computing platforms (personal laptop and Google Colab with Tesla T4 GPU), demonstrating that the issue was environment-specific rather than a fundamental problem with the implementation.

7 Limitations

A primary limitation of this work arises from the scale of the dataset used for training and evaluation. While the proposed pipeline follows the methodology introduced in the original TimeGate study, the dataset employed in this project is considerably smaller than the large-scale Landsat-based dataset used in the reference work. As detailed in the Cloud-Removal report, the experiments were conducted on a limited number of regions of interest and patches, which restricts the diversity of spatial, seasonal, and atmospheric conditions observed during training. As a result, the learned models may not fully capture the wide range of global variability present in large-scale satellite time-series datasets.

Despite the strong performance of the proposed TimeGate-based reconstruction pipeline, additional limitations were observed during experimentation. The most notable failure case occurs when the target region is affected by very thick or persistent cloud cover across the available temporal window. Specifically, the model fails to produce accurate reconstructions when more than 70 percent of the available timestamps contain cloud coverage exceeding 70 percent. In such scenarios, the time series does not contain sufficient valid visual information for the TimeGate mechanism to aggregate meaningful features.

In the validation set of approximately 525 patches, this failure mode was observed in roughly 5 to 8 percent of cases, where cloud coverage was exceptionally heavy throughout the 2018 temporal window. For these samples, SSIM scores dropped significantly, often falling below 0.60, and the reconstructed images exhibited visible artifacts, blurring, or incomplete predictions.

As a result, both the U-Net fusion model and the TerraMind fine-tuned model struggle to accurately reconstruct the underlying surface under extreme cloud conditions. This limitation is inherent to any temporal reconstruction approach that relies on temporal redundancy: without the presence of at least some cloud-free observations in the input sequence, the model lacks sufficient visual information to infer the true ground surface.

8 Future Work

8.1 Short-term Goals

In the short term, we plan to complete comprehensive testing on diverse datasets beyond the 7 ROIs used in this work, to evaluate the model's generalization capability across different geographical regions and climate zones. We will optimize hyperparameters for both pathways through systematic grid search or Bayesian optimization, potentially improving SSIM scores and reducing inference time. We will conduct a more thorough comparative analysis between the U-Net and TerraMind approaches, including detailed ablation studies to understand the contribution of each component. Finally, we will document performance benchmarks across different hardware configurations and create reproducible evaluation protocols.

8.2 Long-term Enhancements

For long-term improvements, we aim to extend the approach to other satellite platforms such as Landsat 8 and MODIS, enabling cross-platform cloud removal capabilities. We plan to implement a real-time processing pipeline that can generate cloud-free imagery on-demand for operational use cases. We will develop ensemble methods that combine both U-Net and TerraMind pathways, potentially leveraging their complementary strengths. We will create a web-based demonstration application that allows users to upload satellite imagery and receive cloud-free outputs. We will explore additional attention mechanisms, such as cross-attention between temporal features and spatial features, to improve reconstruction quality.

Most importantly, we will address the limitation of heavy cloud coverage by integrating complementary data sources such as Synthetic Aperture Radar (SAR) imagery, which is not affected by cloud cover. SAR data provides all-weather, day-and-night observation capability and can serve as a reliable source of surface information even when optical imagery is completely obscured. Additionally, we will investigate expanding the temporal window beyond a single year or incorporating seasonal priors to further improve reconstruction performance under extreme cloud conditions.

9 Project Timeline

The project was executed in seven phases. Phase 1 involved literature review and paper analysis, which has been completed. Phase 2 focused on TimeGate implementation, also completed. Phase 3 covered U-Net development, completed successfully. Phase 4 addressed TerraMind integration, completed on external computing platforms. Phase 5 encompassed testing and validation, which has been completed. Phase 6 involved performance optimization and is ongoing. Phase 7 covers documentation and reporting, currently in progress.

11 Challenges and Limitations

Despite the strong performance of the proposed TimeGate-based reconstruction pipeline, several limitations were observed during experimentation.

The primary limitation arises in scenarios involving **very dense or persistent cloud cover** across the entire temporal window. When a large fraction of the available observations for a patch are heavily cloud-contaminated, the TimeGate mechanism does not have sufficient valid visual information to aggregate meaningful features. In such cases, both the U-Net fusion model and the TerraMind fine-tuned model struggle to accurately reconstruct the underlying surface, leading to blurred or incomplete predictions.

Another limitation relates to the computational requirements of large-scale foundation models. While the TerraMind model demonstrates strong reconstruction capability, fine-tuning is computationally expensive and sensitive to environment- specific dependencies. As discussed earlier, full-scale fine-tuning on the institute infrastructure was not feasible due to compatibility issues, limiting the scope of TerraMind experimentation in this work.

Finally, the current implementation relies solely on optical satellite imagery. Optical data is inherently affected by cloud coverage, which places an upper bound on reconstruction quality when cloud-free observations are sparse.

12 Future Work

Several directions can be explored to extend and improve the proposed framework. A natural extension is the integration of **Synthetic Aperture Radar (SAR)** imagery, such as Sentinel-1 data, which is not affected by cloud cover. Combining optical and SAR modalities could significantly improve reconstruction performance under extreme cloud conditions.

Another promising direction is large-scale and longer-duration fine-tuning of foundation models such as TerraMind using more powerful computing infrastructure. This would enable a more comprehensive comparison between classical encoder–decoder architectures and foundation-model-based approaches.

Future work may also explore adaptive temporal window selection, seasonal priors, and ensemble strategies that combine multiple reconstruction pathways. Finally, deploying the pipeline as an interactive or web-based system could facilitate practical applications in agriculture, environmental monitoring, and disaster response.

13 Conclusion

This project successfully implements a deep learning–based framework for cloud-free satellite image reconstruction by closely following and extending the methodology proposed by Oehmcke et al. Through the use of the TimeGate temporal aggregation mechanism, the system effectively converts multi-temporal satellite image sequences into compact, cloud-aware representations.

By combining TimeGate with a U-Net fusion architecture and exploring fine-tuning of the TerraMind foundation model, the project demonstrates that learned temporal aggregation significantly outperforms simple compositing baselines. Quantitative results using SSIM, PSNR, and MSE, along with qualitative visual analysis, confirm the effectiveness of the approach.

Despite computational and environment-related constraints that limited large-scale foundation model fine-tuning, the conducted experiments provide valuable insights into the trade-offs between classical deep learning models and foundation models for Earth observation tasks. Overall, the project establishes a solid foundation for future research on cloud removal and temporal satellite image reconstruction.
